Abstract- Micromirrors fabricated by MEMS technology have demonstrated to be important sensing or actuating components in many industrial and biomedical applications such as laser scanning displays, optical switch matrices, and biomedical imaging systems. In this paper, various actuation mechanisms for micromirrors are described. A new geometric configuration of a stacked micromirror that is actuated by electrostatic force is proposed and analyzed to show its superior performance in terms of deflection angle, actuation voltage, and frequency response.

Index terms: Micromirror, MEMS, Electrostatic Force Actuation, Deflection Angle, Endoscope, OCT (Optical Coherence Tomography), Stacked Micromirror Configuration

I. INTRODUCTION

Development of MicroElectroMechanical Systems (MEMS) technology in the past decades has benefited automotive, communication and medical industries. Size and mass reduction that are enabled by MEMS technology have improved the performance of devices such as accelerometers, mass-flow sensors, bio-chips, RF devices, and automotive pressure sensors [1]. Popular MEMS devices for optical applications are optical switch arrays for communication [2], Optical Coherence Tomography (OCT) for an endoscope [3], confocal laser scanning microscopy (CLSM) for obtaining high resolution images, and digital micromirror devices for Digital Light Process (DLP) Projection.

MEMS micromirrors used for the above mentioned optical applications can be actuated via electrostatic, magnetic, thermal, and piezoelectric mechanisms. Various actuation mechanisms for sensing are presented in section II. Novel design and analytical modeling of electrostatic actuation of micromirror configuration are presented in section III. Geometry and design of stacked multiple electrode micromirror versus single micromirror configuration are
presented in section IV. Numerical analysis with Finite Element Model (FEM) simulation for each micromirror configuration is discussed in section V followed by the conclusion in section VI.

II. MICROMIRROR ACTUATION METHODS FOR SENSING

2.1 Electromagnetic Actuation:
A micromirror can be deflected in two ways by electromagnetic actuation. First, by using Lorentz force to move a patterned coil by exerting external magnetic field. Second, by repulsive/attractive forces to repel/attract the magnetic material attached to the mirror from/to the actuator [4]. Cugat et al [5] exhibits theoretical potential of magnetic microactuators and systems (MAGMAS) using a permanent magnet in a micro-actuator. Advances in material fabrication to provide thick film deposition of magnetic material on the surface of micro actuators should reduce voltage and current requirements. Magnetic MEMS [6] can offer non-contact operation, and can induce mechanical resonance by magnetic element excitation. However, thermal budget imposed by the current CMOS technology limits the fabrication of the magnetic film on the substrate from reaching the desired characteristics. Large angular scan angle of 8° was achieved with 0.75 mA while showing linear response to the applied current [7].

2.2 Piezoelectric Actuation:
The piezoelectric actuation takes advantage of the corresponding physical deformation to applied electrical voltage property [8]. It has relatively lower operation voltage (3-20 Volt DC) with low power consumption, better linearity, and fast switching time 0.1 to 1.0 milliseconds. For example, Y.Seo et. al has demonstrated 3.93 μm lateral displacement at 16 Volt [9].

2.3 Thermal Actuation:
The main advantage of thermal actuation is the simplicity of the fabrication method. However, in general, thermal actuation tends to have higher power consumption and slow response time. J. Singh et. al [10] demonstrated 10° of angular deflection with approximately 10 ms thermal response time when 1 V was applied to actuate the micromirror. The out-of-plane thermal microactuator uses thermal expansion due to ohmic heating. A thin arm and
wide arm configuration with one end fixed to the substrate has nonlinear property due to temperature dependency [11].

2.4 Electrostatic Actuation:
Despite suffering from the pull-in effect, nonlinear behavior, and higher operating voltage, the electrostatic actuation’s fast response time (less than 0.1 ms), low power consumption, and the easiness of integration and testing with electrical control system make the electrostatic actuation one of the preferred choices for micromirror actuation [12].

The operation voltage of the micromirror can be lowered while achieving more angular deflection if the stiffness of torsion bar is reduced. However, when the stiffness is lowered, the natural frequency of the micromirror also decreases, thereby reducing operational bandwidth. In this paper, two novel configurations of a stacked micromirror are presented. The proposed configuration has the potential to achieve more angular deflection at lower actuation voltage without sacrificing frequency response.

III. ANALYTICAL MODEL OF THE STACKED MICROMIRRORS

In this section, micromirrors of different configurations are presented and compared in terms of their deflection angle and actuation voltage. The conceptual schematics of the three configurations analyzed are shown below. Figure 1(a) shows a conventional micromirror configuration. Figure 1(b) shows a unique configuration of the stacked micromirror also denoted as the first stacked mirror configuration, and Figure 1(c) shows a novel configuration of the stacked micromirror with an offset, which is also known as the second stacked micromirror configuration.

![Figure 1. Schematics of Three Different Micromirror Configurations.](image)

The moving electrode (middle plate) in the stacked configurations is designed to be identical to the micromirror in size and material. Solutions for the following analytical model are independent of the shape and size of the plate (micromirror) as long as the dimensions of each layer are identical.

First, an analytical model of the micromirror is derived to better understand the relationship between each parameter of the micromirror. The torque created by the electrostatic force between the micromirror and its electrodes, as denoted by $M$ for each configuration, is derived from the following dynamic Equation (1):

$$I \frac{d^2 \theta}{dt^2} + c \frac{d\theta}{dt} + k\theta = M \ldots (1)$$

where,
I is the moment of the inertia of the micromirror.

c is the damping coefficient representing the squeeze-film damping.

k is the torsional stiffness of the rotated serpentine spring.

M is the torque created by the electrostatic force between the micromirror and its electrodes.

The moment of the inertia of the micromirror along the y axis is equal to \( \frac{1}{12} ml^2 \).

Second, the value for damping coefficient, c, representing the squeeze-film damping of the micromirror is derived from the linearized Reynold’s equation [13] and presented in Equation (2).

\[
c = \frac{48 \mu ml^8}{\pi^5 (\pi^2 + 4)b^3} \quad (2)
\]

where,

\( \mu \) is the dynamic viscosity of the air.

l is equal to the half length of the micromirror, \( \frac{1}{2} L \).

w is the width of the micromirror.

b is the ratio of the width to the length of the micromirror.

D is the initial air gap between the micromirror and its electrodes.
Third, the torsional stiffness, $k$, of the rotated serpentine spring is derived based on the Equation (3) from work of G. Barillaro et al. [14] and J. You et al. [15]

$$k = \frac{G J_p}{(2N + 2) l_p} \quad \text{(3)}$$

where,

$G$ is the shear modulus of the material used in the rotated serpentine spring.

$J_p$ is the torsion factor of a beam with rectangular cross-section [14] and can be derived from the Equation (4) below.

$N$ is the number of the loops or turns in the rotated serpentine spring.

$l_p$ is the length of the rotated serpentine spring segment that is parallel to the rotation axis.

$$J_p = \frac{tw^3}{a} \left(1 - \frac{192w}{\pi^2} \sum_{l=1,2,3,...}^{\infty} \frac{1}{l^2} \tanh \left(\frac{l\pi}{2w}\right)\right) \quad \text{(4)}$$

Fourth, for the sake of simplicity, the micromirror is considered to be a rigid body and the deflection of the rotated serpentine spring in the $Z$ axis is assumed to be negligible. In order to find the torque created by the electrostatic force between the micromirror and its electrodes, the parallel plate capacitor theory is used to derive the differential force that acts on a small segment of the micromirror and its electrodes:

$$dF = \frac{1}{2} \varepsilon V^2 \frac{w d w}{(D - x \sin \theta)^2} \quad \text{(5)}$$
\[ M = \frac{\varepsilon w V^2}{2} \int_0^L \frac{x}{(D - x \sin \theta)^2} \, dx = \frac{\varepsilon w V^2}{2 \sin^2 \theta} \left\{ \frac{L \sin \theta}{D - L \sin \theta} + \ln \left(1 - \frac{L}{D} \sin \theta \right) \right\} \] \quad \text{(6)}

where,

\( \varepsilon \) denotes the permittivity of air.

\( V \) represents the potential difference between the micromirror and its electrode.

Last, the normalized angle, \( \varphi \), and the maximum deflection angle, \( \theta_{\text{max}} \), are defined as the following:

\[ \varphi = \frac{\sin \theta}{\sin \theta_{\text{max}}} \approx \frac{\theta}{\theta_{\text{max}}} \quad \text{and} \quad \theta_{\text{max}} = \sin^{-1} \left( \frac{L}{D} \right) \approx \frac{L}{D} \quad \text{if} \quad \theta \ll 1 \quad \text{and} \quad \theta_{\text{max}} \ll 1 \] \quad \text{(7)}

The torque, \( M \), for each configuration is simplified with the normalized angle \( \varphi \) as represented by the following Equation (8) (9) and (10):

\[ M_0 = \frac{1}{2} \varepsilon w V^2 \frac{L^2}{D^2 \varphi^2} \left( \frac{\varphi}{1 - \varphi} + \ln(1 - \varphi) \right) \] \quad \text{(8)}

\[ M_1 = \frac{1}{2} \varepsilon w V^2 \frac{L^2}{D^2} \left( \frac{2\varphi}{1 - 2\varphi} + \ln(1 - 2\varphi) \right) \] \quad \text{(9)}

\[ M_2 = \frac{1}{2} \varepsilon w V^2 \frac{L^2}{D^2 \varphi^2} \left( \frac{1}{1 - 2\varphi + \varphi^2} \right) \] \quad \text{(10)}
where, $M_0$ represents the torque created in the single mirror configuration. $M_1$ and $M_2$ denote the torque generated in the first and second stacked mirror configurations, respectively. To simplify the analysis, the fixed bottom electrodes are not used to actuate the micromirrors in both stacked configurations.

![Torque vs Angle Comparison Plot](image)

**Figure 2. Torque versus Angle Comparison Plot for Three Micromirror Configurations.**

To visualize the magnitude of torques against the normalized angles, the normalized torques of $M_0$, $M_1$, and $M_2$ are plotted in the Figure 2. The red line shows an exponential increase in the normalized torque as the normalized angle grows. The black line (conventional single mirror configuration) shows relatively gradual increase. As expected, while the deflection angle is small there are negligible differences between the three configurations in terms of the torque created by the same actuation voltage. However, as the deflection angle increases, the torque acting on the first stacked mirror grows exponentially. On the other hand, the second stacked mirror configuration shows a 50% increase in torque when compared to the single mirror configuration.
IV. GEOMETRY

The size and geometry of the micromirror are determined by the diameter of the optical beam as well as its application. For example, a micromirror used in an endoscope would require a smaller form factor. In this paper, the micromirror is designed to be 1 mm in length, 1 mm in width and 10 μm in thickness. Also, it is assumed to be made of polysilicon that has a Young’s modulus of 160 GPa, Poisson’s ratio of 0.22 and density of 2330 kg/m³. Normally, the micromirror is designed to be suspended over a cavity by two torsion bars. Even though a straight torsion bar is simple to design and fabricate, it suffers from residual stress, which alters the stiffness of a torsion bar and the micromirror’s frequency response. Furthermore, modification of the physical or geometric properties of the straight torsion bar is not straightforward since the geometry of the torsion bar such as the width and thickness are limited by the fabrication process. Hence, two rotated serpentine springs are chosen to hold the micromirror in place while the micromirror rotates. The serpentine springs’ stiffness can be easily customized regardless of the fabrication process. The rotated serpentine spring is well analyzed in [14] and has already been demonstrated [15]. Thus, a rotated serpentine spring is employed in this analysis. The rotated serpentine spring used in this analysis is 4 μm wide, 10 μm thick, and 100 μm in length from one end to another end. The gap between each turn is 4 μm. Figure 3(a) shows the expanded view of the rotated serpentine spring, and Figure 3(b) shows the relative size and location of the spring on the micromirror.

Figure 3. (a) Rotated Serpentine Spring Torsion Bar and (b) the Micromirror.
Two different configurations of the micromirror are presented in Figure 4. To simplify modeling and analysis, the geometry and material of the plates (micromirrors) are kept identical except the stacking configuration. As shown in Figure 4(a), a micromirror is placed 250 μm directly above another square plate along the z-axis. In Figure 4(b), a micromirror is placed above another mirror with a 250 μm gap in the z-axis and a 500 μm offset along the x-axis. The top plate is the micromirror, and the bottom plate is used as moving electrodes.

The micromirror and its moving counterpart have two electrodes located on their bottom. The electrodes are assumed to be made of 1 μm aluminium thin film. The rotated serpentine springs provide electrical connection between the electrodes and control circuitry.

Figure 4. Stacked Micromirror Configurations.
V. NUMERIAL ANALYSIS AND RESULTS

In this section, numerical analyses using COMSOL® are presented. The results are followed by a discussion on the static deflection that is caused by varying actuation voltages.

5.1 Finite Element Analysis (FEA):

The finite element models (FEM) are similar to the earlier analytical models other than the fact that the fixed bottom electrodes are located on the substrate. Three finite element models are created to represent each micromirror design configuration: (i) a single mirror with fixed bottom electrodes as shown in Figure 5(a); (ii) a stacked mirror on top of each other as shown in Figure 5(b); and (iii) a stacked mirror with an offset as shown in Figure 5(c). As mentioned before, the micromirror and its moving electrodes have the same size and material properties. Since all micromirrors are actuated by the electrostatic force, the air gap between the micromirror and its electrodes is also meshed with the arbitrary Lagrangian-Eulerian (ALE) method.

![Figure 5. FEMs of the Three Micromirror Configurations.](image)

5.2 Static Analysis:

In this static analysis, the DC voltage is increased gradually to find the deflection of the far edge of the moving plate (micromirror). The static analysis results of the three different configurations are shown in Figure 6. Both stacked mirrors show more deflection as the
actuation voltage increases. At low actuation voltage, there is not much difference in deflection, since the initial air gap between the micromirror and its electrodes is the same (250 μm). However, the difference in deflection becomes clear at higher actuation voltage until the pull-in occurs. Furthermore, the micromirror in the first stacked configuration shows the most deflection. The reason is that charges are concentrated at the far edge of the micromirror, where the gap between the micromirror and its electrodes is the smallest. Thus, the surface charge density is the highest in the far edge thereby creating the most torque. On the contrary, the charges are uniformly distributed in the second stacked micromirror configuration with an offset, since the air gap along the surface is quite uniform while rotating. Therefore, less torque is generated. The black line (single micromirror configuration) shows the least deflection in the z-axis. The blue line shows the response of the stacked micromirror with an offset configuration. The red line (stacked micromirror without an offset) shows the most deflection in the z direction.

![Deflection in the Z axis](image)

**Figure 6. Static Analysis Results of the Three Micromirror Configurations.**

Figure 7 shows the simulation results in 3-D. The micromirrors and their moving electrodes are colour-mapped by their deflection in the Z axis. The most deflection is shown in red and less deflection in dark blue. For this static analysis, the fixed bottom electrodes in all three configurations are used to actuate the micromirrors. That is the reason that the moving electrodes underneath the micromirrors are rotated more than the micromirror themselves.
5.3 Normal Mode Analysis:

The normal mode analysis is performed to find the natural frequency of the micromirror using COMSOL®. Its first natural frequency is found to be 543 Hz when rotating about the Y- axis as shown in Figure 8(a). The second harmonic frequency is 3,602 Hz as a rectilinear motion along the Y axis (Figure 8(b)). The third harmonic frequency is 3,910 Hz as a rectilinear motion along the Z axis (Figure 8(c)). The fourth natural frequency is 5,268 Hz as a rectilinear motion along the X axis (Figure 8(d)). Note that the damping is not considered in this eigenfrequency analysis.
5.4 Frequency Response Analysis:

For a scanning micromirror, its high frequency performance is more important than its static performance. Most scanning micromirrors operate at their natural frequency to increase the scanning angle with a low actuation voltage. Both frequency response with and without damping are shown in Figure 9. In this damped frequency response analysis, only the squeeze-film damping is considered and structural damping is not included. By adding the damping only lowered the first natural frequency by 3 Hz. However, approximately 18 dB less amplification is attributed to damping effect at the natural frequency.
5.5 Transient Analysis:

A 500Hz input AC voltage, with a fixed 80 Volts DC bias, is applied to find the transient performance of the micromirror. As mentioned before, most scanning micromirrors operate at their resonant mode to further increase its scanning angle. The control voltage signal is 
\[ 80 \sin(2\pi \cdot 500t) + 80. \]
VI. CONCLUSIONS

Two different stacked micromirror configurations are studied and numerically analyzed in this paper. Its analytical model is also derived to facilitate comparisons of its performance against a conventional single micromirror. Then, its FEM is created and simulated in COMSOL® to show better static and transient performance over the others. Even though the moving electrodes in this design are assumed to be identical to the micromirror in terms of its size and torsional stiffness, changes to the electrodes can be made to meet a specific application. Furthermore, this concept can be easily extended to a 2 Degree-of-Freedom micromirror.
